Background of the Invention

Field of the Invention

20

The present invention relates generally to the field of integrated circuit manufacturing, and more specifically, to copper alloy interconnections and their formation.

Background

25

Advances in semiconductor manufacturing technology have led to the development of integrated circuits having multiple levels of interconnect. In such an integrated circuit, patterned conductive material on one interconnect level is electrically insulated from patterned conductive material on another interconnect level by films of material such as, for example, silicon dioxide. These conductive materials are typically a metal or metal alloy. Connections between the conductive material at the various interconnect levels are made by forming openings in the insulating layers and providing an electrically conductive structure such that the patterned conductive material from different interconnect levels are brought into electrical contact with each other. These electrically conductive structures are often referred to as contacts or vias.

35

EL034438229US

- 5 Other advances in semiconductor manufacturing technology have led to the integration of millions of transistors, each capable of switching at high speed. A consequence of incorporating so many fast switching transistors into an integrated circuit is an increase in power consumption during operation. One technique for increasing speed while reducing power
- 10 consumption is to replace the traditional aluminum and aluminum alloy interconnects found on integrated circuits with a metal such as copper, which offers lower electrical resistance. Those skilled in the electrical arts will appreciate that by reducing resistance, electrical signals may propagate more quickly through the interconnect pathways on an integrated circuit.
- 15 Furthermore, because the resistance of copper is significantly less than that of aluminum, the cross-sectional area of a copper interconnect line, as compared to an aluminum interconnect line, may be made smaller without incurring increased signal propagation delays based on the resistance of the interconnect. Additionally, because the capacitance between two electrical
- 20 nodes is a function of the overlap area between those nodes, using a smaller copper interconnect line results in a decrease in parasitic capacitance. In this way, replacing aluminum-based interconnects with copper-based interconnects provides, depending on the dimensions chosen, reduced resistance, reduced capacitance, or both.
- 25 As noted above, copper has electrical advantages, such as lower resistance per cross-sectional area, the ability to provide for reduced parasitic capacitance, and greater immunity to electromigration. For all these reasons, manufacturers of integrated circuits find it desirable to include copper in their products.

5 While copper is electrically advantageous as compared to aluminum for interconnect lines in integrated circuits, pure copper interconnect lines may still suffer from electromigration related defects.

 Accordingly, there is a need for providing copper-based interconnections on integrated circuits that have improved levels of
10 electromigration resistance.

Brief Description of the Drawings

Detailed Description

Methods of introducing dopants into copper interconnect structures, and the resulting copper alloy interconnect structures are described. In the following description numerous specific details are set forth to provide an
20 understanding of the present invention. It will be apparent, however, to those skilled in the art and having the benefit of this disclosure, that the present invention may be practiced with apparatus and processes that vary from those specified herein.

Reference herein to "one embodiment", "an embodiment", or
25 similar formulations, means that a particular feature, structure, or characteristic described in connection with the embodiment is included in at least one embodiment of the present invention. Thus, the appearances of such phrases or formulations herein are not necessarily all referring to the same embodiment. Furthermore, various particular
30 features, structures, or characteristics may be combined in any suitable manner in one or more embodiments.

Terminology

10

15

25

The term vertical, as used herein, means substantially perpendicular to the surface of a substrate.

30

5 process. A damascene process may also be referred to as an in-laid
metal process. Unlike the subtractive etch processes used to form
aluminum and aluminum-based interconnect lines, copper and copper-
based interconnect lines are typically produced by first forming a
dielectric layer, patterning the dielectric layer to provide recessed
10 portions, referred to as trenches, covering the dielectric layer, including
the trenches, with copper or a copper-based metal, and removing that
portion of the copper or copper-based metal that is outside of the
trenches, typically by chemical mechanical polishing, to thereby form
individual interconnect lines. In other words, the metal remaining in the
15 trenches are the individual interconnect lines. Typically, the top surface
of the dielectric layer and all the surfaces of the trenches are covered
with a barrier layer prior to the deposition of the copper or copper-based
metal. The material that makes up the barrier layer is chosen such that
the barrier is resistant to the passage of copper atoms therethrough.
20 Copper diffusion barrier layers include, but are not limited to, Ta, TaN,
TaSiN, W, WN, WSiN, Ti, TiN, TiSiN, and Co. Copper diffusion barriers
may be formed from electrically non-conductive materials as well as from
conductive materials, although an electrically conductive copper
diffusion barrier is typically used. A barrier layer can be deposited by
25 physical vapor deposition (PVD), chemical vapor deposition (CVD) or
atomic layer deposition (ALD). A seed layer is typically formed over the
barrier layer to facilitate the deposition of the copper or copper-based
metal layer. The seed layer, whether formed of Cu or a Cu alloy, can be
deposited by PVD, CVD, or ALD. Cu alloy seed layers can be used with
30 or without barrier layer if the Cu alloy acts as the required diffusion
barrier.

If, in addition to trenches, deeper openings in the dielectric layer
EL034438229US

It has been demonstrated that by adding small amounts of a second metallic species to copper interconnect lines, the electromigration lifetime of those Cu interconnects is significantly improved.

In some embodiments of the present invention, a dopant layer is formed over a copper layer and the dopant is driven into the subjacent copper layer. More particularly, and with reference to Figs. 1 and 2, a layer of copper **104** is plated over a dielectric layer **102** on a wafer to fill the trenches **103** and via openings **104** of a dual damascene structure. A layer **106** containing at least one alloying element is then deposited over plated copper layer **104**, typically to a thickness in the range of 0.5 to 1.0 micron. This alloying element may also be referred to as a dopant, and layer **106** containing the alloying element may be referred to as the dopant layer. Elements that may be used as dopants for improving the electromigration characteristics of the interconnect lines include, but are not limited to, Sn, Al, and Mg.

EL034438229US

- 5 interconnect structure is a reduction in conductivity compared to pure Cu. With respect to the illustrative dopants, Sn, Al, and Mg, in each case, the amount of dopant is in the range of 0.1 atomic % to 2 atomic %.

Fig. 3 summarizes the operations of an illustrative process in accordance with the present invention. A copper layer is formed overlying a
10 patterned dielectric layer (302). Consistent with a damascene metallization process the patterning of the dielectric layer is for the purpose of forming trenches and via openings, and typically the patterned dielectric layer has a copper diffusion barrier disposed thereon over which the copper layer is disposed. A doped layer is subsequently formed superjacent the copper
15 layer (304). The doped layer may be electroplated or formed in any other suitable manner. The doped layer contains at least one element which, when alloyed with copper, improves the electromigration characteristics the copper. By way of example and not limitation, Al, Mg, Sn, and Co are doping species that can improve the electromigration performance of copper. In particular,
20 Sn, and Sn containing metals can be plated onto the copper layer in a known manner. Dopants from the doped layer are thermally driven into the underlying copper layer (306). Such a thermal drive-in is typically conducted in the range of 300°C to 400°C.

Implanted Dopants

- 25 In some embodiments of the present invention, a dopant element is introduced into a local region of the copper interconnect structure by ion implantation. By limiting the doped regions to a near-surface portion of the copper interconnect structure, improved electromigration characteristics can be achieved without reducing the conductivity of the entire interior portion of
30 the copper interconnect structure. Additionally, such surface doping

- 5 treatments may provide improved adhesion between the interconnect lines and adjacent layers of dielectric material.

In one embodiment, prior to introduction of dopants by ion implantation, a copper damascene structure is formed in a conventional manner. For example, in a dual damascene process, trenches and via
10 openings are formed in an oxide-based interlayer dielectric material. A copper diffusion barrier is formed over the surfaces of the interlayer dielectric including the surfaces of the trenches and via openings. A seed layer is formed over the barrier layer, and copper is then plated over the seed layer. Copper may be plated by an electroplating process or by an electroless
15 deposition process. Excess portions of the copper layer and barrier layer, that is, those portions overlying the top surface of the interlayer dielectric, are removed, typically by chemical mechanical polishing, thereby leaving the individual interconnects. The surface of the wafer after polishing presents a first portion which is the top surface of the interlayer dielectric, and a second
20 portion which is the top surface of the individual interconnect lines.

Doping elements are then implanted over the surface of the wafer. Such doping elements may include, but are not limited to, Sn, Al, and Mg. Where the elements are implanted into the copper interconnect lines, a copper alloy is formed that improves the electromigration characteristics of
25 the interconnect lines. Where the elements are implanted into the surface of the interlayer dielectric, a non-conductive stable oxide is formed. These post-CMP implants into the copper are very shallow, typically on the order of ten monolayers. Both Al and Mg implants may be performed with a dose of 3×10^{15} atoms/cm² at an energy of 5keV. The dose and energy settings for ion
30 implantation in this illustrative embodiment were chosen to provide an implant profile with a peak at 50 angstroms below the Cu surface and an average of

5 1.5 wt% dopant over 100 angstroms. No special temperature or atmosphere
is required for activation of the implanted species. Subsequent to
implantation of dopant species, a barrier layer is deposited over the surface
of the wafer. The barrier layer may be formed from materials such as, but not
limited to, silicon nitride and silicon carbide. The barrier layer is preferably
10 formed from a material that substantially or completely prevents diffusion of
copper therethrough and into the surrounding dielectric layers. Such a layer
may also function as an etch stop layer for subsequent process operations
such as the formation of via openings. Fig. 4 shows the features of a
structure formed in this way. More particularly, a dielectric layer **102** that has
15 been patterned to accommodate a trench and a via opening, has a copper-
diffusion barrier layer **403** disposed thereon as shown. A copper-based
interconnect line **104** is shown bounded by barrier layer **403** and implanted
region **404**. Implanted region **404** is that portion which provides for improved
electromigration performance both in terms of current carrying capacity and
20 lifetime. Regions **402** represent the surface of dielectric layer **102** which have
been implanted with the same dopant species as the copper-based
interconnect line. These dopants typically form a non-conductive metal oxide
when implanted into dielectric layer **102**. The implanted regions **402**, **404** are
covered by a barrier layer **406**. Barrier layer may also serve as an etch stop
25 layer for subsequent manufacturing operations.

Implanting Al or Mg into the copper interconnect lines has been found
to improve electromigration characteristics by approximately 50% to 100%
with only an approximately 5% increase in resistance. In particular, the 50%
to 100% improvement refers to an increase in current carrying capability
30 while maintaining the same lifetime from the point of view of reliability.
Generally, a 2X increase in current carrying capability results in a 4X increase
in lifetime.

5 Fig. 5 is a flow diagram illustrating the operations in an illustrative embodiment of the present invention in which localized alloy regions are formed by ion implantation. A copper layer is formed overlying a patterned dielectric layer (502). Excess metal is removed so as to form individual copper interconnect lines (504) in accordance with typical damascene
10 metallization processes. Dopants are then implanted into at least the interconnect lines (506). In a presently preferred embodiment, a blanket implant is performed in which both the individual copper interconnect lines and the surrounding dielectric regions are implanted with the dopant species. In this scenario, the implanted species preferably forms an electrically non-
15 conductive compound with the dielectric layer. For example, with an oxide-based dielectric layer and an Al implant, an aluminum oxide is formed in the dielectric regions.

Variations of such an implanted process may include protecting the dielectric regions from implantation by forming a masking layer over the
20 dielectric regions, or forming a barrier/etch stop layer over the post-CMP surface of the substrate and implanting through.

Doped Seed Layer

In some embodiments of the present invention, a dopant element is introduced into a local region of a copper interconnect structure by
25 outdiffusion from a doped seed layer. In such embodiments, a doping element is co-deposited with the Cu seed layer over the copper-diffusion barrier. It is possible in such a process for the doping element or elements co-deposited with the seed layer to oxidize. When the doping element or elements are oxidized, partially or completely, the ability to
30 form the desired copper alloy is reduced or eliminated. In accordance with the present invention, in order to prevent some or all of the dopant

- 5 in the seed layer from oxidizing, a capping layer is formed over the doped seed layer.

In one illustrative embodiment, the capping layer is formed by depositing copper over the doped seed layer. More particularly, a seed layer of copper, which is doped with an alloying element, is deposited by magnetron sputtering, and a Cu capping layer is then deposited without breaking vacuum. In this way, the doped seed layer is protected from oxidation by the overlying copper capping layer. In addition to physical vapor deposition, the copper capping layer may be deposited by way of a self-ionizing plasma (SIP). Similarly, if the dopant species is susceptible of an SIP deposition, then the doped seed layer may also be deposited by SIP. Fig. 6 illustrates a barrier/seed/cap stack in accordance with the present invention. A dielectric layer **102** is patterned to form a trench and via opening. A copper-diffusion barrier layer **602** is disposed over the surfaces of dielectric **102**. A doped seed layer **604** is disposed over copper-diffusion barrier layer **602**. A capping layer **606** comprised of Cu is disposed over doped seed layer **604**.

- After capping layer **606** is deposited, a Cu layer is formed overlying capping layer **606**. This Cu layer is typically formed by electroplating but may also be formed by an electroless deposition. Dopants from the seed layer are then thermally driven into the overlying Cu layer. As noted above, although the dopant will improve the electromigration characteristics of the Cu interconnect lines, it will also undesirably increase the resistivity of the lines. For example, the change in resistivity is approximately 0.6 micro ohm-cm/atomic % Mg added to Cu; approximately 1 micro-ohm-cm/atomic % Al added to Cu;

- 5 approximately 3 micro-ohm-cm/atomic % Sn added to Cu; and
approximately 4 micro-ohm-cm/atomic % Si added to Cu.

To obtain the benefits of electromigration improvements without a substantial resistance penalty, it is desirable to concentrate the dopants at an upper portion of the Cu interconnect lines. In order to facilitate the
10 movement of the dopant to the upper surface of the Cu, the concentration gradient from the doped seed layer to the upper portion of the Cu is modified by a chemical reaction, in accordance with the present invention. This chemical reaction is initiated to draw the dopant out of the upper surface of the Cu such that more dopant diffuses to the
15 upper portions of the Cu to take the place of the dopant consumed by the chemical reaction. By way of illustration and not limitation, if the dopant is Sn and oxygen is introduced during the thermally driven dopant diffusion, then Sn reaching the surface of the Cu reacts to form a tin oxide. In this way the equilibrium concentration of Sn at the upper
20 portions of the Cu is modified, thereby resulting in Sn continuing to move towards the upper portion of the Cu. Nitrogen may also be used to react with a dopant species to form, for example, a nitride.

Fig . 7 is a flow diagram illustrating an embodiment of the invention in which a doped seed layer having a capping layer is formed.
25 First, a dielectric layer is patterned to form at least trenches therein (702). Of course, via openings may also be formed as is common in a dual damascene process. Formation of trenches and via openings is well known in this field and therefore the details of such formation are not further described in detail herein. A copper-diffusion barrier layer is
30 formed over the surfaces of the patterned dielectric layer (704). The barrier layer may be formed of any suitable material that substantially

5 reduces or prevents the diffusion of copper atoms into the dielectric layer. A doped seed layer is then deposited over the barrier layer (706). Such doped seed layers include, but are not limited to CuMg and CuSn, and may be deposited by physical vapor deposition or other suitable deposition techniques, such as, but not limited to, a self-ionizing plasma
10 deposition. By way of illustration and not limitation, the CuMg seed layer may contain 0.7 wt% Mg, and the CuSn seed layer may contain 0.5 wt% Sn. Such doped seed layers may have a thickness in the range of 1500 angstroms to 3000 angstroms. Those skilled in the art and having the benefit of this disclosure will recognize that various ranges of dopant
15 concentrations and seed layer thicknesses may be used within the scope of the present invention. The doped seed layer may be deposited in an AMAT 5500 Endura platform, available from Applied Materials of Santa Clara, California. A capping layer is then deposited without exposing the doped seed layer to the atmosphere (708). The capping layer may be
20 deposited in-situ, that is, in the same chamber in which the doped seed layer is deposited without breaking vacuum. In this way the dopant is not oxidized before the capping layer is in place to prevent the undesired oxidation of the dopants. In this illustrative embodiment, the capping layer is formed by PVD of Cu. It is preferable to perform an in-situ
25 deposition of the capping layer in the same tool without breaking vacuum to prevent oxidation of the underlying dopants. By way of illustration and not limitation, the capping layer formed of Cu may be 1500 angstroms thick.

Fig . 8 is a flow diagram illustrating an embodiment of the
30 invention in which a doped seed layer having a capping layer is formed, and in which a chemical reaction is initiated at the surface of a subsequently deposited layer of Cu in order to alter the distribution of

EL034438229US

After a copper alloy is formed in which dopants are preferably distributed near the upper portions thereof, excess portions may be removed so as to form individual interconnect lines. Removal of excess portions is typically accomplished by chemical mechanical polishing.

Embodiments of the present invention provide copper-based interconnections that include alloy, or doping, elements that improve the electromigration characteristics of such interconnections as compared to pure copper interconnections. Various strategies for introducing the desired

- 5 doping elements into the copper-based interconnections are described, including thermally driving in dopants from an overlying dopant layer, implanting dopants, and outdiffusing dopants from an underlying doped seed layer.

10 An advantage of some embodiments of the present invention is that adhesion of various dielectric materials to the copper alloy is improved as compared to pure copper.

 An advantage of some embodiments of the present invention is that the electromigration resistance of copper-based interconnects is improved as compared to pure copper.

15 An advantage of some embodiments of the present invention is that the adhesion between the copper alloys and the barrier layer is improved relative to that of pure copper.

20 Other modifications from the specifically described apparatus, materials, and processes may be apparent to those skilled in the art and having the benefit of this disclosure. Accordingly, it is intended that all such modifications and alterations be considered as within the spirit and scope of the invention as defined by the subjoined Claims.
